Abstract (193 words)

Human Long Intergenic Noncoding RNA-p21 (LincRNA-p21) is a regulatory noncoding RNA that plays an important role in promoting apoptosis. LincRNA-p21 is also critical in downregulating many p53 target genes through its interaction with a p53 repressive complex. The interaction between LincRNA-p21 and the repressive complex is likely dependent on the RNA tertiary structure. Previous studies have determined the two-dimensional secondary structures of the sense and antisense human LincRNA-p21 AluSx1 IRs using SHAPE. However, there were no insights into its three-dimensional structure. Therefore, we in vitro transcribed the sense and antisense regions of LincRNA-p21 AluSx1 Inverted Repeats (IRs) and performed analytical ultracentrifugation, size exclusion chromatography, light scattering, and small angle X-ray scattering (SAXS) studies. Based on these studies, we determined low-resolution, threedimensional structures of sense and antisense LincRNA-p21. By adapting previously known twodimensional information, we calculated their sense and antisense high-resolution models and determined that they agree with the low-resolution structures determined using SAXS. Thus, our integrated approach provides insights into the structure of LincRNA-p21 Alu IRs. Our study also offers a viable pipeline for combining the secondary structure information with biophysical and computational studies to obtain high-resolution atomistic models for long noncoding RNAs.

1.0 Introduction

The tumour suppressor protein p53 is an important transcription factor that regulates a variety of cellular processes, including cell-cycle control, DNA repair, apoptosis, senescence, and cellular stress responses through the activation and repression of target genes [1, 2]. Despite playing a critical role in the DNA damage response, p53's genome is frequently mutated in cancer cells, exposing a vulnerability in cell cycle regulation [3, 4]. Nevertheless, when DNA damage occurs, p53 upregulates the expression of genes involved in the cell cycle arrest and DNA repair processes, which leads to cell survival, but also facilitates the initiation of apoptosis for cancerous cells [5]. Regulation of p53 is generally achieved through post-transcriptional modification, which can include its phosphorylation, acetylation, methylation, ubiquitination, or SUMOylation with the result of different types of DNA damage affecting p53's activation [6, 7]. The p53 pathway itself is composed of a network of genes, regulatory proteins, and their transcriptional products which can help respond to intrinsic and extrinsic stress signals [8]. This can include MDM2 which interacts strongly with p53 and helps regulate its activity through post-transcriptional modification. MDM2 degrades p53 through the ubiquitin proteasome pathway and prevents the transcription of tumour suppressor genes leading to apoptosis [9-11]. Other proteins like the acetyltransferase P300 can also enhance the activity of p53 [12]. These networks enable the regulation of p53 and can be additionally modulated by long noncoding RNAs (LncRNAs) which have been shown to act in a regulatory role within the p53 pathway. Often, the transcription of LncRNA genes are the targets of p53 itself [13-16].

LncRNAs are noncoding RNA molecules devoid of an open reading frame and are generally around 200-100,000 nucleotides (nts). They also do not retain any significant proteincoding capabilities and are therefore generally not expressed [17-19]. LncRNAs were previously thought to have no biological function but have been identified to regulate biological processes by altering gene expression and signal pathways [17]. Consequently, LncRNAs play a role in the regulation of gene expression and appear poised to affect the progression of cancers. Long intergenic noncoding RNA-p21 (LincRNA-p21) is found to be a transcriptional repressor in the p53 pathway, playing a role in triggering cellular apoptosis [20]. LincRNAs are also capped, spliced, and polyadenylated due to being RNA polymerase II transcripts [18]. Under stress conditions including DNA damage, p53 activates the transcription of LincRNA-p21 which accumulates in the nucleus and associates with the heterogeneous nuclear ribonuclear protein K (hnRNP-K) [21]. The hnRNP-K contains RNA recognition motifs Arg-Gly-Gly repeats or hnRNP-K homology (KH) domains and whose role is important for nucleic acid metabolism and transcription [22, 23]. The hnRNP-K is integral in the induction of apoptosis since it will combine with the p53 promoted and transcribed LincRNA-p21 which will then act to repress p53 target genes resulting in apoptosis [24]. LincRNA-p21 is thus required to help direct hnRNP-K to bind to the promoters of the target repressed genes [23]. Additionally, hnRNP-K was observed to be a transcriptional coactivator of p53, enabling gene expression in response to DNA damage [22].

An important element identified in the LincRNA-p21 gene is the presence of two isoforms that contain Alu repeats, which influence the function of the RNA [21]. Alu elements are particularly important because they are highly conserved among primates and fold to produce independent domains. These repeated DNA sequences comprise upwards of 60% of the human genome and can be divided into several classes including micro-satellites (repeat sequences greater than 7 bp), mini satellites (basic repeats of 7 bp or less), or telomeres. These interspersed repeated DNA sequences are further divided into two classes: Short interspersed elements (SINES), and

long interspersed elements (LINES) [25]. Alu SINES themselves are repetitive elements present in multiple copies of the genomes they reside in and are named because the family of repeats contains a recognition site for the restriction enzyme AluI [26, 27]. Full-length Alu elements are roughly 300 bp long and are frequently located in the 3'-untranslated regions of genes and their intergenic genomic regions and continue to be the most abundant mobile or transposable element in the entirety of the human genome. Alu elements are also important because they maintain an impact on the human genome's mutability [26]. Alu elements can influence insertion mutations, recombination between elements, gene conversion, and gene expression, and can ultimately cause human diseases including neurofibromatosis, haemophilia, hypercholesterolaemia, breast cancer, insulin-resistant diabetes type II, and Ewing sarcoma [28-30]. Determining the structural-dependent role of LincRNA-p21 Alu elements will have an impact on elucidating their overall function and responsibilities within the cell.

Many studies using molecular and computational structural biology seek to identify LncRNA secondary and tertiary structures, and whether said structures have an impact on their function [31, 32]. This also includes the application of RNA secondary structure prediction techniques such as selective 2'-hydroxyl acylation analysed by primer extension (SHAPE) [33]. Doing so is important because it conceptualises structures present on LincRNA-p21 and can elucidate potential specific interactions within the p53 and hnRNP-K pathways. Previous studies have investigated the secondary structure of LincRNA-p21 Alu Inverted Repeats (IRs) and identifying important functional regions that are involved in LincRNA-p21 nuclear localisation and its subsequent transcriptional factor interactions [21]. They identified that the two isoforms of LincRNA-p21 Alu IRs retained integral secondary structures that can fold into independent domains. These structures were suggested to be conserved in primates and contribute towards the regulation of cellular localisation of LincRNA-p21 during the cellular stress response.

Incidentally, the intent of this study is to investigate the overall structure of the sense and antisense LincRNA-p21 *AluSx1* Inverted Repeats by employing small angle X-ray scattering (SAXS) and computational modelling to develop their three-dimensional structures [34]. We have employed analytical ultracentrifugation (AUC) and size exclusion chromatography coupled to multiangle light scattering (SEC-MALS) instruments to biophysically characterise transcribed and purified *AluSx1* RNAs. AUC experiments revealed that *AluSx1* RNAs were present as monomeric, full-length transcripts under denaturing conditions, while SEC-MALS characterised their Molecular Weight (Mw). By combining chemically probed secondary structure information proposed by Chillón and Pyle, 2016, and SimRNA computational modelling, several three-dimensional, high-resolution models can be calculated and fitted to SAXS determined structures. We determined that LincRNA-p21 *AluSx1* RNA adopts an asymmetrical, and extended structure in solution. We describe a workflow utilising SAXS and SimRNA computational modelling to produce three-dimensional, high-resolution models devised from two-dimensional structures determined *via* SHAPE and other secondary structure probing techniques.

2.0 Methods

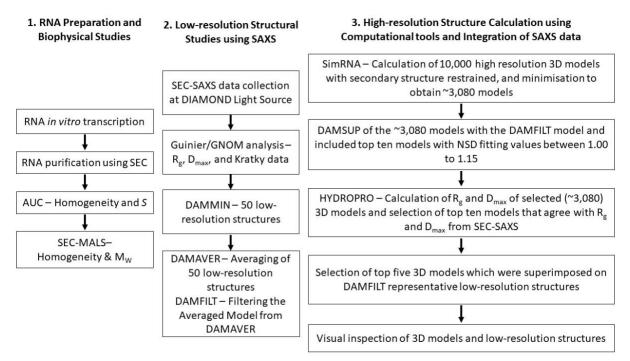

Figure 1: Organisational Flowchart for the Purification and Characterisation of Sense and Antisense LincRNA-p21 AluSx1 RNA. The determination of LincRNA three-dimensional, low-resolution structures overlaid by high-resolution, atomistic models was conducted in three phases: RNA preparation and biophysical studies to determine sample homogeneity and sample properties; low-resolution structure determination by SAXS; and high-resolution modelling using SimRNA, with constraints imposed by HYDROPRO. All methods are further described below.

2.1 Sense and Antisense LincRNA-p21 AluSx1 Plasmid Preparation

A flowchart of the procedure is outlined in **Figure 1**. LincRNA-p21 *AluSx1* transcripts for the sense and antisense (taken from the TP53COR1 gene located on Chr6:36,663,392-36,667,296 (GRCh38/hg38), Chr6:36,631,169-36,635,073 (GRCh37/hg19)) were designed from the sequences presented in from Chillón and Pyle [20, 21]. RNA constructs used in this experiment are represented below:

>LincRNA-p21 AluSx1 Antisense RNA Sequence (280nt) | TP53COR1_LIsoE2_AluSx1_P

LincRNA-p21 *AluSx1* RNAs will be referred to as sense and antisense *AluSx1* RNAs throughout. The plasmids were synthesised commercially, each sequence was flanked by a T7 RNA polymerase promoter sequence at the 5' end and an *XbaI* restriction endonuclease cut-site sequence at the 3' end. To increase RNA yield, two additional Gs were added to the 3'-end of the T7 promoter region which is reflected in the theoretical Mw (**Table 1**) [35]. LincRNA-p21 sequences were inserted into Genewiz pUC-57-KAN plasmids (Azenta Life Sciences, USA). Plasmids were transformed and cultured in *E. coli* NEBα (NEB, Canada) competent cells and were purified using NEB Monarch Miniprep Kits (NEB, Canada) as per manufacturer's protocol.

2.2 In vitro Transcriptions of LincRNA-p21 Sense and Antisense AluSx1 Inverted Repeats and RNA Purification

RNA transcripts were prepared using run-off in vitro transcriptions (IVT) as prepared previously [36, 37]. Briefly, concentrated plasmid samples were digested by *XbaI* restriction endonuclease (NEB, Canada). 1 mL in vitro transcription reactions were performed using laboratory purified inhouse T7 RNA polymerase and commercial RiboLock RNase inhibitor (Thermo Fisher Scientific, USA) [38]. Linearised plasmids were additionally incubated with 10% DMSO and 0.1% Triton X-100 to increase RNA transcript yields [39]. Sense and antisense AluSx1 RNA were purified by SEC using a Superdex 200 Increase GL 10/300 (Global Life Science Solutions USA LLC, Marlborough, MA, USA) and purification buffer (PB) (10 mM Bis-tris pH 5.0, 100 mM NaCl, 15 mM KCl 15 mM MgCl2, 10% glycerol) with an ÄKTA pure FPLC (Global Life Science Solutions USA LLC, Marlborough, MA, USA) [40]. SEC peak fractions were assessed for purity by ureapolyacrylamide gel electrophoresis (Urea-PAGE) and sedimentation velocity analytical ultracentrifugation (SV-AUC) in 6M urea. Urea-PAGE (10%) was run at room temperature, 300V, for 40 min in 1x TBE (Tris-Borate-EDTA) buffer, followed by staining with SybrTM Safe (Thermofisher Scientific, Saint-Laurant, QC, Canada) and visualisation. Pure fractions were pooled and concentrated by ethanol precipitation, with resuspension in HEPES Folding Buffer (HFB) (50mM HEPES, 150 mM NaCl, 15 mM MgCl₂, 3% Glycerol, pH 7.4) for SAXS submission.

2.3 Multiangle Light Scattering (MALS), and Analytical Ultracentrifugation (AUC) Studies of LincRNA-p21 *AluSx1* Sense and Antisense Inverted Repeats

SEC purified LincRNA-p21 *AluSx1* RNAs were subjected to an additional SEC purification by a Superdex 200 Increase 10/300 GL column in HFB and analysed directly by an in tandem DAWN Multiangle Light Scatterer (MALS) with Optilab Refractive Index System (Wyatt Technology, USA) to determine the Mw as per Wyatt Technologies guidelines [41]. Samples were eluted at a 0.5 mL/min flowrate and measured using 18 multiangle detectors, including a UV A₂₆₀ and A₂₈₀, and a refractive index (RI) detector. MALS measurements were taken using a helium-neon red

laser (632.8 nm) at 25°C. For data analysis, the refractive index increment (dn/dc) was adjusted to 0.1721 mL/g for sense and antisense *AluSx1* RNA samples [42-44]. Data were analysed using the ASTRA v9 software package (Wyatt Technology, USA) [45, 46].

Purified sense and antisense AluSx1 RNA were measured by SV-AUC under denaturing conditions in 6M urea to ascertain purity and composition of the transcript. Both samples were measured in two-channel centrepieces and spun at 25,000 rpm for 6 hours at 20°C. Denaturing 6M urea buffer density (1.0899 g/mL) and viscosity (1.3896 cP) were estimated with Ultrascan and used to convert observed sedimentation and diffusion coefficients to standard conditions (water at 20°C). Data were collected in intensity mode at 260 nm and processed using the UltraScan III Software [47]. SV-AUC data were processed as described in [48]. Briefly, systematic noise contributions and boundary conditions (meniscus and bottom of the cell position) samples were processed with the two-dimensional spectrum analysis [49]. Data was further refined by genetic algorithm analysis to achieve parsimonious regularisation [50]. The final step included a genetic algorithm-Monte Carlo (GA-MC) analysis, that was performed with 50 iterations to obtain 95% confidence intervals for the determined parameters (Table 1) [51]. AUC data analysis was performed on the XSEDE high-performance computing infrastructure using Expanse and Bridges-2 at the San Diego and Pittsburgh supercomputing centres, respectively. The final model produced very low residual mean square deviations (RMSD) of 0.00139 at 0.438 OD₂₆₀ for sense and 0.00177 at 0.71 OD₂₆₀ for antisense LincRNA-p21 AluSx1. All fits produced random residuals, which, together with the low RMSD is evidence for excellent convergence.

2.4 Small Angle X-Ray Scattering (SAXS) Analysis of LincRNA-p21 *AluSx1* Sense and Antisense

SAXS data for sense and antisense *AluSx1* RNA samples were collected at 2.5 mg/mL. Samples were run at Diamond Light Source Ltd. synchrotron (Didcot, Oxfordshire, UK) on the B21 SAXS beamline, with a high-performance liquid chromatography (HPLC) system attached upstream to ensure sample monodispersity [52]. A specialised flow cell was employed in conjunction with an inline Agilent 1200 HPLC system (Agilent Technologies, Stockport, UK); sense and antisense *AluSx1* RNA samples were injected onto a Shodex KW403-4F (Showa Denko America Inc., New York, NY, USA) size exclusion column pre-equilibrated with HFB. The flow rate of the column was maintained at 0.160 mL/minute with eluted samples being exposed to X-rays with 3 second exposure time and 600 frames.

Analysis of scattering data was carried out using the ATSAS suite [53]. Using Chromixs, the buffer contribution was subtracted from the sample peak [54]. A Guinier analyses (q^2 vs. ln(I(q))) was performed on each data set to obtain the radius of gyration (R_g) and to determine the sample's quality [55]. A dimensionless Kratky plot (qR_g vs $qR_g^{2*}I(q)/I(0)$) was generated to evaluate folding of RNA molecules [56]. A paired-distance distribution function (P(r) analysis was performed using GNOM to obtain real-space R_g and the maximum particle dimension (P(r)) and the sample [57]. Employing the information derived from the P(r) plot, a total of fifty sense and antisense AluSxI RNA models were generated using DAMMIN [58]. These models were then averaged using DAMAVER and then filtered using DAMFILT to produce a single representative model of each of the RNAs [58, 59].

2.5 Sense and Antisense LincRNAp-21 AluSx1 RNA Tertiary Structure Determination

Using the secondary structure information from Chillón and Pyle, 2016, sense and antisense *AluSx1* tertiary structures were calculated using SimRNA v3.20 [34]. SimRNA v3.20 is a Monte Carlo sampler that operates on a coarse-grained model of RNA structure. SimRNA employs a five-bead system per nucleotide, as well as an empirically derived knowledge-based potential. A total of 20 million SimRNA iterations in replica exchange mode were performed for both sense and antisense *AluSx1* RNAs. SimRNA clustering was then performed within one percent of all trajectories with the lowest energy. A RMSD cut-off of five was applied to filter 3080 clusters of similar structures for both sense and antisense *AluSx1* RNAs.

2.6 High-Resolution Structural Modelling of LincRNA-p21 *Alu*Sx1 Sense and Antisense

The representative cluster models containing 3080 computationally generated high-resolution models for both the sense and antisense AluSx1 were separately assessed by HYDROPRO to generate hydrodynamic properties for each model [60]. Running conditions for HYDROPRO involved buffer properties for HFB as determined by UltraScan III: a viscosity of 1.10068 cP; and buffer density of 1.014 g/cm³ [47]. The theoretical Mw of 99.418 kDa and 89.543 kDa were applied to the HYDROPRO parameters of sense and antisense AluSx1 RNA, respectively. Models were superimposed onto the SAXS DAMFILT structures and fitted using DAMSUP. Models exhibiting an NSD (normalized spatial discrepancy) value of 1.00 to 1.15 which indicates close fitting were further selected to represent the high-resolution, atomistic RNA model [59]. Models exhibiting similar HYDROPRO determined Rg and Dmax were further selected for and formed the top ten models of interest. The top ten models were energy minimised using an additional step involving QRNAS, which employed a subset of the AMBER force field to achieve energy minimisation of the structures generated from coarse-grained three-dimensional modelling [61]. 20,000 QRNAS MD iterations were performed from the original SimRNA full-atom reconstructed high-resolution models that best-fit the averaged, filtered low-resolution, three-dimensional structure obtained from DAMFILT. Subsequently, five best fit models were superimposed on SAXS structures and represented using PyMOL [59, 62].

3.0 Results

3.1 Purification of LincRNA-p21 Sense and Antisense AluSx1 Inverted Repeats

Both sense and antisense *AluSx1* RNAs were purified using SEC, eluting principally around ~10.0 – 12.5 mL at a flowrate of 0.5 mL/min on the Superdex 200 Increase GL 10/300 (**Figure 2A**). The left peak indicates plasmid excluded from subsequent analysis while the right peak represents the RNA of interest. **Figure 2B** depicts the 10% Urea PAGE gel for the RNA fractions indicating that both RNAs migrated closely with similar length and, around the ~300bp marker. Sense LincRNA-p21 *AluSx1* generally produced closely eluting bands (around ~300bp). SV-AUC experiments were conducted using the single fractions collected at 11.0 mL and 11.5 mL for sense and antisense *AluSx1* RNA respectively (indicated by the right shoulder, blue inset, **Figure 2A**).

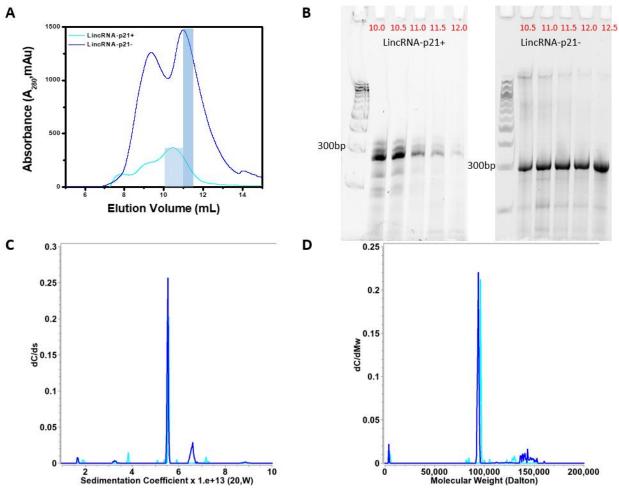

Figure 2: Purification of Sense and Antisense *in vitro* **Transcribed LincRNA-p21** *AluSx1* **RNA.** (A) depicts the size exclusion chromatogram of the sense and antisense *AluSx1* RNA elution profile using the Superdex 200 Increase GL 10/300 column. SEC-MALS and SV-AUC experiments were performed with the fractions highlighted in light blue (sense) and dark blue (antisense). (B) shows the 10% urea PAGE gel used to ascertain the sense and antisense LincRNA-p21 RNA purity extracted using 0.5 mL fractions (volumes in red) using an ÄKTA Pure FPLC through a Superdex 200 Increase GL 10/300 SEC column. Fractions collected at 11.0 mL and 11.5 mL for sense and antisense *AluSx1* purifications were consolidated and used for SAXS and SV-AUC experiments. A Quick-Load® Purple 100 bp DNA Ladder (NEB, Canada) was used for the 10% urea PAGE gels in lanes 1 and 7 of each gel. (C) dC/ds sedimentation coefficient distributions for sense (light blue) and anti-sense (dark blue) under 6M urea denaturing conditions. (D) same as (C), except transformed to molar mass distributions assuming a partial specific volume of 0.516 mL/g.

3.2 Biophysical Characterisation of LincRNA-p21 Sense and Antisense AluSx1 Inverted Repeats

Sedimentation and diffusion coefficients and their 95% confidence intervals resulting from the GA-MC analyses are listed in **Table 1**. Together with sequence based molar masses, SV-AUC results can be used to derive partial specific volumes and anisotropies for the RNA measurements. Since both RNA molecules were measured in the same urea buffer, it is reasonable to assume that the partial specific volume is similar for both molecules. Sedimentation experiments were performed in 6M urea to denature the molecule and disrupt hydrogen bonding within double-stranded RNA regions of the molecule. Results shown in **Figure 2C** and **Figure 2D** indicate that

both samples contain one major species with similar sedimentation coefficients, and molar masses in agreement with molar masses predicted from sequence when using a partial specific volume of 0.516 mL/g. This result is consistent with a monomeric and homogeneous full-length transcript of sense (84% of total concentration) and antisense (75% of total concentration) LincRNA-p21 *AluSx1* RNA. Frictional ratios and hydrodynamic radii derived for both molecules indicate a high anisotropy for both molecules, consistent with an unfolded and extended molecule.

SEC-MALS analysis was conducted to determine the Mw of the sense and antisense *AluSx1* RNA SAXS. LincRNA-p21 *AluSx1* RNAs were purified again on a Superdex 200 Increase GL 10/300 SEC column which produced peaks eluting between 11 – 12.5 mL (**Figure 3A**). Mw values of sense and antisense *AluSx1* reported from SEC-MALS are slightly higher than the molar masses calculated from their sequences except for sense LincRNA-p21 *AluSx1* which exhibited less than 0.2% difference from the theoretical Mw at 99.24 ± 0.01 kDa (**Table 1**). Mw uniformity throughout **Figure 3B** and **Figure 3C** indicates that both RNAs are monomeric. SEC-MALS results further confirm the homogeneous composition of sense and antisense *AluSx1* RNA determined in SV-AUC. RNA degradation or shorter transcripts can be excluded since no significant smaller fragments were detected. Hydrodynamic parameters derived from SEC-MALS, and SV-AUC are summarised in **Table 1**.

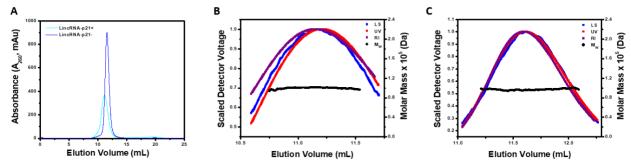

Figure 3: Molecular Weight Determination of Sense and Antisense LincRNA-p21 *AluSx1* RNA using SEC-MALS. (A) Portrays the elution curve from the Superdex 200 Increase GL 10/300 SEC of sense and antisense *AluSx1* RNAs. (B) Demonstrates the absolute molecular weight distribution across the elution peak of sense LincRNA-p21 *AluSx1* RNA's elution profile, and light scattering (blue), UV (red), and RI (purple) scattering. (C) Portrays the absolute molecular weight distribution across the elution peak the results fitting of antisense LincRNA-p21 *AluSx1* RNA's elution profile, and light scattering (blue), UV (red), and RI (purple) scattering.

Table 1: Solution Properties of Sense and Antisense LincRNA-p21 AluSx1.

Sample	Sense LincRNA-p21 AluSx1	Antisense LincRNA-p21 AluSx1
M_w Theoretical (kDa)	99.418	89.543
M_w AUC (kDa) ⁺	94.770	92.561
M_w SEC-MALS (kDa) $^{\nabla}$	99.24 ± 0.01	94.52 ± 3.71
Sedimentation Coefficient, $s_{20, w} (10^{-13} s)^+$	5.56 ± 0.25	5.53 ± 0.05
Diffusion Coefficient, $D_{20, w} (10^{-7} \text{ cm}^2/\text{s})^+$	2.95 ± 0.59	3.00 ± 0.03
Frictional Ratio, f/f ₀ +	2.71	2.68
R_h (Å) $^+$	72.7	71.3
$q.R_g$ range #	0.43-1.29	0.42-1.25
R_{g} (Å) #	60.87 ± 0.85	59.07 ± 0.15
I(0) ^Δ	$0.01 \pm 9.90 \times 10^{-5}$	$0.07 \pm 8.14 \times 10^{-5}$
R_{g} (Å) $^{\Delta}$	61.71 ± 0.31	58.37 ± 0.07
D_{max} (Å) $^{\Delta}$	185.0	180.7
X ² *	~1.148	~1.084
NSD *	1.080 ± 0.024	1.005 ± 0.022

The M_W of the sense and antisense LincRNA-p21 Alu Repeat RNA were calculated using the nucleotide sequences provided by Chillón and Pyle, 2016. *Molar masses and frictional ratios determined by AUC assume a partial specific volume of 0.516 mL/g and refer to conditions where the RNA is denatured by 6M urea. *are within 95% confidence intervals. Data points ∇ were determined from SEC-MALS experiments. Data points # were derived from the Guinier analysis. Data points Δ were determined using P(r) analysis using the GNOM program. Data points * were derived from DAMMIN and DAMAVER analysis. Terms: Hydrodynamic Radius (R_h); Radius of Gyration (R_g); Maximum Particle Dimension (D_{max}); Normalised Spatial Discrepancy (NSD).

3.3 Low-Resolution Structural Studies of LincRNA-p21 Sense and Antisense AluSx1 Inverted Repeats

SAXS is a powerful method that can represent the overall solution shape of biomolecules under physiologically relevant conditions. Using SEC-SAXS, which can separate different species according to their size before being applied to the SAXS measuring cell, provides confidence in the monodispersity of purified samples [63-66]. The resulting datasets were merged and presented in **Figure 4A** depicting the scattering intensity relative to angle for sense and antisense AluSxI RNA. A Guinier analysis (l(q)) vs. (q²)) represented by **Figure 4B** displays the LincRNA-p21 AluSxI RNA samples' purity [55]. The Guinier analysis determined the Guinier R_g from the low-q region as being 60.87 ± 0.87 Å for sense LincRNA-p21 AluSxI and 59.07 ± 0.15 Å for antisense LincRNA-p21 AluSxI. Intensity data from **Figure 4A** was transformed to produce a dimensionless Kratky plot (**Figure 4C**) to determine the LincRNA-p21 AluSxI RNAs' conformations in solution [67]. The dimensionless Kratky plot for both the sense and antisense AluSx1 shows a levelled-plateau which suggests them as being folded and extended in solution [68].

Figure 4D represents the (P(r)) plot which was derived from indirect Fourier transformations to convert the reciprocal-space information of the intensity data in **Figure 4A** to real-space electron pair distance distribution data [69]. Using the P(r) plot, sense LincRNA-p21

AluSx1 presented a real-space R_g of 61.71 \pm 0.31 Å and a D_{max} of 185.0 Å, while the antisense LincRNA-p21 AluSx1 presented a real-space R_g of 58.37 \pm 0.07 Å and D_{max} of 180.7 Å.

DAMMIN was performed to obtain low-resolution structures for the sense and antisense *AluSx1* RNA. Fifty models were calculated for each sense and antisense *AluSx1* RNAs which demonstrated favourable agreement as indicated by the X^2 values (~1.148 for sense LincRNA-p21 *AluSx1* and ~1.084 for antisense LincRNA-p21 *AluSx1*). DAMFILT and DAMAVER were performed to filter and averaged the models. The NSDs were estimated to be 1.080 \pm 0.024 and 1.005 \pm 0.022 for sense and antisense respectively (**Table 1**) [62].

We identified two, single representative SAXS envelopes illustrated by **Figure 5**. The averaged, single-representative SAXS envelope of sense LincRNA-p21 *AluSx1* is generally extended, adopting a non-spherical, nonglobular surface model (**Figure 5A**). The SAXS envelope is additionally asymmetrical in its rotation along its x- and y-axes, exhibiting two prominent bulges that are primarily located on its ends. **Figure 5B** shows the antisense LincRNA-p21 *AluSx1* SAXS envelope which is similarly elongated and asymmetrical. Antisense LincRNA-p21 *AluSx1* though has three prominent bulges, two located centrally, while the third distally protrudes outwards from the centre.

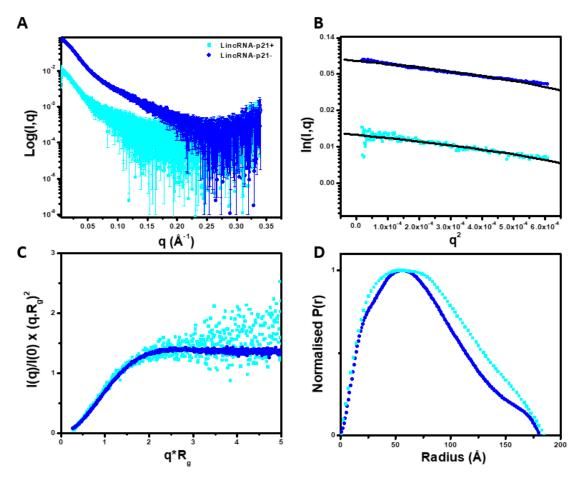

Figure 4: Small Angle X-Ray Scattering (SAXS) Characterisation of Sense and Antisense LincRNA-p21 AluSx1 RNA. (A) merged scattering data of sense and antisense AluSx1 RNA depicting the scattering intensity (log I(q)) vs. scattering angle ($q = 4\pi \sin\theta/\lambda$). (B) Guinier plots allowing for the determination of R_g from the low-angle region data and representing the homogeneity of samples. (C) Dimensionless Kratky plots (I(q)/I(0)*(q*R_g)2 vs. q*R_g) of sense and antisense AluSx1 RNA depicting the elongated, tube-like structures because of the non-Gaussian, levelled-plateau

shape of the curve. (**D**) Normalised pair distance distribution plots for sense and antisense AluSxI RNA which permits the determination of R_o derived from the SAXS dataset and including each molecule's D_{max} .

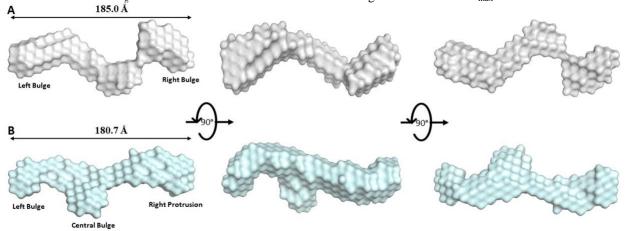

Figure 5: Low-Resolution Structures of Sense (A, Grey) and Antisense (B, Pale Cyan) LincRNA-p21 AluSx1 Inverted Repeats Determined using SAXS. (A) The averaged DAMAVER SAXS low-resolution structure of sense LincRNA-p21 AluSx1 RNA, taking on an elongated, asymmetrical, and extended structure with maximum length of 185.0 Å. Key features include a left and right Bulge. (B) The averaged DAMAVER SAXS low-resolution structure of antisense LincRNA-p21 AluSx1 RNA, adopting an elongated, asymmetrical, and extended structure with maximum length of 180.7 Å. Key features include a left bulge, central bulge, and a right protrusion. Dimensions are represented by the D_{max} obtained from the P(r) analysis. Models are rotated along their x-axis by 90° as represented by the inset.

4.2.4 High-Resolution Atomistic Models of LincRNA-p21 AluSx1 Sense and Antisense Inverted Repeats

Using SimRNA v3.20, and the secondary structure constraints for both RNAs based on previous studies, we calculated 10,000 clusters of high-resolution, atomistic models for each RNA [21]. These models were further refined through energy minimisation steps to remove models that did not satisfy constraints such as defined atom distances, bond lengths and angles. Subsequently, we obtained 3080 high-resolution models that can be superimposed on the DAMFILT SAXS envelopes using DAMSUP. Sense LincRNA-p21 *AluSx1* models when superimposed produced ten models that had an NSD range from 1.053 to 1.094, while for the antisense RNA, the top ten models retained an NSD range of 1.113 to 1.175. We further applied a selection process using the real-space R_g and D_{max} values determined from SAXS for each molecule. We employed the program HYDROPRO to calculate biophysical properties such as R_g and D_{max} from the 3080 high-resolution models, as performed previously [70]. Top ten models were further reduced to five using the HYDROPRO properties to achieve models that were in close approximations to SAXS determined R_g and D_{max}.

Both the top five high-resolution, high-fidelity sense and antisense *AluSx1* models are represented by **Figures 6** and **7** respectively. **Figure 6** depicts the sense LincRNA-p21 *AluSx1* RNAs that closely fit with the SAXS envelopes generated in **Figure 5A**. Previous chemically probed secondary structure predictions identified three major secondary structures: a left and right arm, and a 3'-three-way junction which have been modelled using SimRNA and represented in **Figure 6**. High-fidelity sense LincRNA-p21 *AluSx1* characteristically exhibits the right arm (Magenta) that curls into the central RNA body while the left arm (Blue) extends outwards. Multiple models depict variance in the right arm's position, appearing to adopt multiple conformations that curl, but rarely extend outwards, towards the central RNA body. The right

arm's stem-loop on its head is additionally compacted and has either bridged with the main RNA body against the 3'-three-way junction or curls outwards. We have identified a consistent 3'-adenyl tail (Cyan) that consistently wraps around the right arm's base or the connection with the 3'-three-way junction (Yellow). A 5'-junction (Green) is also a present feature identified but not named by the previous study, but consistently appears to project outwards, perpendicularly from the RNA's x-axis (**Figure 6**). A flexible, and generally unnamed region – the single-stranded linker (Orange), is presented centrally between the two arms, adopting no specific structure.

Figure 7 similarly presents the high-fidelity, high-resolution structures of antisense LincRNAp21 *AluSx1* which were modelled using previous chemically probed secondary structure predictions using SimRNA v3.20 [21]. They exhibit the left and right arms, and the 5'-three-way junction. Both the left (Blue) and right (Magenta) arms of antisense LincRNA-p21 *AluSx1* project laterally in line with the x-axis. The identified 5'-uridyl tail (Cyan) consistently wraps around the left arm. Both the 3'-three-way junction, and the identified 5'-junction are compacted centrally, with regions that project perpendicularly from the RNA body's x-axis. The right arm of antisense LincRNA-p21 *AluSx1* does not retain the characteristic stem-loop head that sense LincRNA-p21 *AluSx1* has.

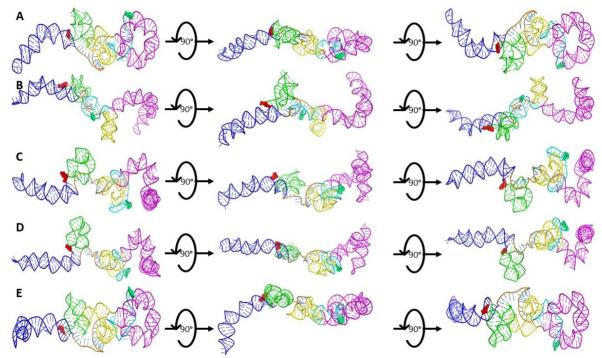

Figure 6: The SimRNA High-Resolution, High-Fidelity Models of Sense LincRNA-p21 *AluSx1* **RNA. Figure 6** presents the high-resolution, high-fidelity sense models that have good fitting with their SAXS envelope as demonstrated by low NSD values. **A** represents model 514; **B** represents model 1036; **C** represents model 1476; **D** represents model 1677; and **E** represents model 1794 which exhibit chemically probed secondary structures: left arm (Blue); 5'-junction (Green); three-way junction (Yellow), right arm (Magenta), and the 3'-adenyl tail (Cyan). Terminal nucleotides are displayed as: 5'nt (Red, Sphere Modelled) and 3'nt (Lime Green, Sphere Modelled). Models are rotated along their x-axis by 90° as indicated by the inset. A flexible, single-stranded linker sequence is represented centrally (Orange).

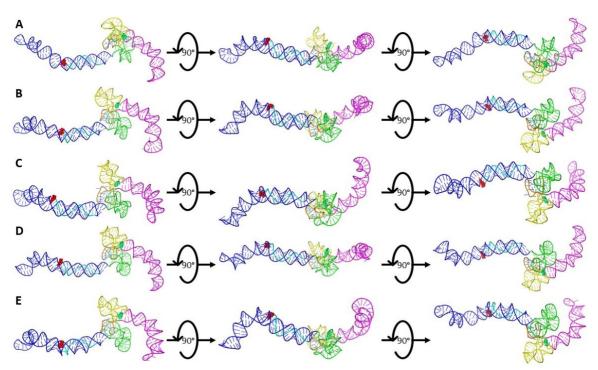

Figure 7: The SimRNA High-Resolution, High-Fidelity Models of Antisense LincRNA-p21 *AluSx1* RNA. Figure 7 presents the high-resolution, high-fidelity sense models that have good fitting with their SAXS envelope as demonstrated by low NSD values. A represents model 66; B represents model 974; C represents model 1013; D represents model 1074; and E represents model 1417 which exhibit chemically probed secondary structures: left arm (Blue); 5'-junction (Green); three-way junction (Yellow), right arm (Magenta), and the 5'-uridyl tail (Cyan). Terminal nucleotides are displayed as: 5'nt (Red, Sphere Modelled) and 3'nt (Lime Green, Sphere Modelled). Models are rotated along their x-axis by 90° as indicated by the inset. A flexible, single-stranded linker sequence is represented centrally (Orange).

After performing DAMSUP, the high-fidelity, high-resolution models were visually inspected in terms of their alignment with the low-resolution SAXS envelope from DAMFILT and were represented in **Figures 8** and **9** for sense and antisense *AluSx1* RNA respectively. **Figure 8** displays a general agreement with the sense SAXS envelope overlaid by their high-fidelity, high resolution SimRNA models. Both the left and right arms when superimposed fit neatly within the protruding two bulges of the SAXS envelope. Minor disagreement occurs for the right arm's stemloop head which appears to be excluded from the SAXS structure, which is similar for the tip of the Left arm. Both the 5'-junction and 3'-three-way junction exhibits considerable overlap with the SAXS low-resolution structure when superimposed. **Figure 9** shows a general agreement with the antisense SimRNA models with their respective SAXS low-resolution structures. The left arm, 5'-junction, and 3'-three-way junction are secondary structures that exhibit the highest relative overlap with the SAXS envelope and occur within the central bulge and right-most protrusion. The right arm (Magenta) depicts relatively lower agreement, with its tip and core regions exposed and externalised from the SAXS envelope. This is primarily confined to the left bulge, however, which indicates a lack of adequate fitting.

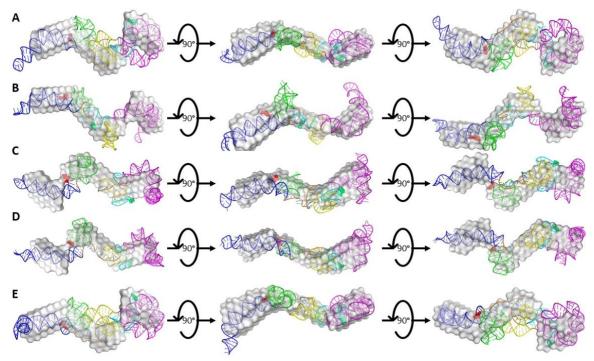

Figure 8: Superimposed Overlays of Sense SAXS Envelopes with their High-Resolution, High-Fidelity SimRNA Models. Figure 8 represents the combined overlays of the sense LincRNA-p21 *AluSx1* RNA envelope with their top high-resolution, SimRNA models: (A) 514; (B) 1036; (C) 1476; (D) 1677; and (E) 1794. Overall, SAXS envelopes indicate a general agreement with computationally generated structures, showing high overlap of the extended molecule with the major secondary structures identified using chemical probing techniques.

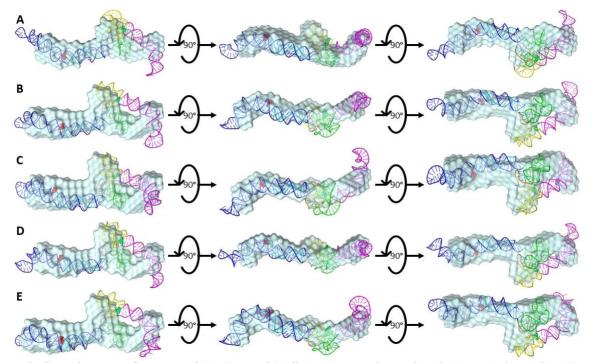

Figure 9: Superimposed Overlays of Antisense SAXS Envelopes with their High-Resolution, High-Fidelity SimRNA Models. Figure 9 represents the combined overlays of the antisense LincRNA-p21 *AluSx1* RNA envelope with their top high-resolution, SimRNA models: (A) 66; (B) 974; (C) 1013; (D) 1074; and (E) 1417. Overall, SAXS envelopes indicate a general agreement with computationally generated structures, showing high overlap of the

extended molecule with the major secondary structures identified using chemical probing techniques. However, there is a slight overhang present with the right arm (Magenta) which has an area excluded from overlapping with the SAXS envelope.

4.0 Discussion

RNA secondary structure is especially important in defining an RNA molecule's roles and functions [71, 72]. These structures can be studied using a variety of techniques including secondary structure probing methods such as SHAPE, NMR, comparative sequence alignment and analysis, or three-dimensional structure predictions software for conceptualising higher order complexes [73-76]. Identifying functional structural elements of RNA is especially important when observing the noncoding elements of the genome, whose significant contribution of noncoding RNA (ncRNA) play important regulatory roles in complex organisms. LincRNA-p21 is one such important regulatory lncRNA that is directly targeted by p53 in response to DNA damage. Being a transcriptional repressor in the p53 pathway, understanding LincRNA-p21's secondary structure is a first step evaluation towards how it binds to and modulates hnRNP-K localisation which is a process that ultimately triggers apoptosis in DNA damaged or cancerous cells.

The primary intent of our work is to obtain the high-resolution details of LincRNA-p21 *AluSx1* RNA by combining the previously determined secondary structure of the Inverted Repeat transposable elements determined by Chillón and Pyle with SAXS structure determination and computational modelling [21]. **Figure 1** outlines our multifaceted process for biophysically characterising molecules using SEC-SAXS, SEC-MALS, SV-AUC, and SimRNA from chemically probed secondary structure determinations. SEC-MALS and AUC act as orthogonal quality control and validation techniques when combined with PAGE [77].

We initially started by transcribing sense and antisense AluSx1 RNAs, which were purified to homogeneity as indicated by **Figure 2A**. Both RNA displays multi-modal peaks with a primary peak representative of the monomeric RNA species. Fractions along the primary peak were taken and analysed by 6M urea PAGE, which showed relatively pure and pronounced RNA bands around 300 bp indicating that most of the species is the primary RNA of interest (Figure 2B). Subsequent urea PAGEs were performed, and each resulted in an inconclusive answer to RNA homogeneity. We therefore turned to SV-AUC to determine if the RNA samples were heterogenous as indicated by urea-PAGE, or homogenous enough for further characterisation. As indicated in **Figure 2C**, **D**, both sense and antisense AluSx1 RNA adopted a single, major species in solution when denatured by 6M urea. Any minor species had negligible concentrations and reflected noise contributions. The SV-AUC experiments showed no evidence for RNA degradation or aggregation. The Mw values of sense and antisense AluSx1 RNAs determined by AUC were less than 5% different (Table 1). AUC experiments were carried out in the presence of 6M urea as a denaturant, so we needed to assess each RNA in non-denaturing conditions. We therefore utilized SEC-MALS to determine absolute molecular weight in solution [41, 78]. Each RNA eluted as a singular, tight, and gaussian distribution elution profile evident in Figure 3A. Comparatively to AUC results, the RNA also exists monomerically in HFB as indicated by their uniform Mw demonstrated in Figures **3B/C.** The sense RNA molecular weight resulted in 99.24 \pm 0.01, virtually identical to the theoretical molecular weight of 99.42 kDa. Antisense RNA also resulted in a very similar molecular weight of 94.52 ± 3.71 to the theoretical value of 89.54 kDa. These results suggest the RNA was acceptable to undergo SEC-SAXS and three-dimensional structure determination since SAXS requires highly homogenous samples.

SAXS is an ideal technique to determine low-resolution three-dimensional structures of molecules in their native state and was used to investigate the solution conformations of both RNAs [58, 79, 80]. Overall, scattering intensities were acceptable even in low-angle regions as shown in **Figure 4A**. The linear regression of the sense and antisense AluSxI samples in **Figure 4B** portrays the intensities within the defined low- q^2 range as being linear with the absence of upward curves, illustrating monodispersity and the absence of attractive or repulsive interactions between scatterers [68, 81, 82]. Guiner R_g approximation resulted in 60.87 ± 0.85 and 59.07 ± 0.15 for sense and antisense AluSxI RNAs respectively. These Rg approximations are consistent with an elongated RNA molecule [83, 84]. Furthermore, the relative foldedness of sense and antisense RNAs can be deduced from the dimensionless Kratky plot in **Figure 4C**. The Kratky plot depicts both sense and antisense RNAs as being elongated but relatively folded, like other ncRNA [36, 85]. Additionally, the Guinier R_g and the real-space R_g are close with less than 1.5% difference.

Figure 4D represents both RNA's distance distribution functions and are non-Gaussian, further consistent with extended molecules. Globular molecules will generate a Gaussian-like P(r) distributions which is not demonstrated in **Figure 4D** further justifying its extended shape [69]. Using the P(r) distribution, molecules can also be described on their overall shape and symmetry to confirm solution folding acquired from the dimensionless Kratky plot [69]. Generally, globular molecules will display a bell-shaped curve with a maximum at approximately D_{max}/2 while elongated molecules retain non-Gaussian, asymmetrical distributions with a maximum at smaller distances which appear as shoulders. For elongated molecules, this distribution will correspond to the radius of the cross section which will generally be illustrated by a tailing of the profile at larger distances [36, 86]. This is present for both sense and antisense AluSx1 RNA whereby their respective D_{max}/2 do not demonstrably produce an even bell-curved but rather lead into rightleaning tails reinforcing the overall elongated shape established by **Figure 4C**. Sense and antisense adopt maximum distance towards 185.0 Å and 180.7 Å respectively. Both RNAs result in similar D_{max} measurements which is expected of two RNA of similar lengths, with the sense RNA being larger than the antisense RNA. These size difference can be attributed both to the RNAs' folding properties, and the 307nt vs 280nt lengths of the sense and antisense sequences as derived from Chillón and Pyle [21].

SAXS analysis of both the sense and antisense RNAs provided structures with noticeably consistent features, including a left and right bulge for the sense RNA and a left and central bulge, and right protrusion for the antisense RNA (**Figure 5**). Use of the standard HFB was important since human LincRNA-p21 folds at near physiological concentrations at around 5mM MgCl₂ with maximum compaction at 15mM MgCl₂ [21]. These features are observed to overlap with predicted features seen in the secondary structure analysis by Chillion and Pyle [21]. These features, while they can be seen in the SAXS structures, were arbitrarily based on structure orientation because directionality cannot be determined from these models. Therefore, we needed to not only computationally derive higher resolution models for clarity, but also directionality.

When analysing the high-resolution computational models derived from the secondary structure determinations, a straitened selection process was needed to screen for models that match the experimentally determined low-resolution structures. Therefore, HYDROPRO was employed to compute the hydrodynamic properties of sense and antisense *AluSx1* rigid macromolecules from their atomic-level structure [87-90]. HYDROPRO's calculation comprise the basic hydrodynamic properties including the translational diffusion coefficient, sedimentation coefficient, intrinsic viscosity, and relaxation times, and can additionally provide the radius of gyration [60]. Incidentally, HYDROPRO can be used as another orthogonal selection process against

computationally generated models that don't fit the solutions scattering data. It was employed to minimise the $\sim\!3080$ models which could subsequently be fit using DAMSUP based on the solution scattering range of D_{max} and R_g . Consequently, observing HYDROPRO merely as a fitting tool narrowed the selection of potential models to five.

As detailed in Figures 6 and 7, sense and antisense AluSx1 RNA folds into a doublestranded RNA molecule that appear to be consistent with Chillón and Pyle's secondary structure determinations. Human LincRNA-p21 is itself a linear, single exon lncRNA which contains IR Alu repeats such as AluSx1 [21]. Both the sense and antisense AluSx1 RNAs were determined to comprise a left and right Arm with both arms connected by a single-stranded region. The 5' domain of each arm is characterised by a central three-way junction while the 3' domain is characterised by a long stem-loop. These subsequently form independent structural domains which contribute to a variety of core functions such as human LincRNA-p21's nuclear localisation following cell stress and DNA damage events [20]. They suggested that the 5' end of LincRNA-p21 interacts with hnRNP-K which could also regulate its nuclear localisation in conjunction with its AluSx1 inverted repeat elements. Our low-resolution, three-dimensional structure of sense LincRNA-p21 AluSx1 RNA (**Figure 8**) exhibits what appears to be two dsRNA arms that fold helically into the otherwise elongated, but radially compact model. When overlaid with the SAXS envelope, considerable overlap is present between the high-fidelity, high-resolution models. Both the 5'-junction and 3'three-way junction are tightly localised in the centre of the RNA body, while the left and right arms branch outwards. This likely forms a binding pocket or coordination site for hnRNP-K's one of three KH RNA/DNA binding domains which is involved in eliciting transcription regulation in the nucleus [91-93]. Antisense LincRNA-p21 AluSx1 RNA is again represented as a dsRNA molecule with both the 5'-junction and 3'-three-way junction being compressed around the central bulge of the SAXS envelope (Figure 9). The RNA molecule itself is mostly extended with the left and right arms projecting outward which likely contributes towards interacting with hnRNP-K RNA binding domains.

Agreement of solution structure and computational models for sense LincRNA-p21 AluSx1 as evident by high overlaps and tight fitting. However, tangible exclusions are present for antisense LincRNA-p21 AluSx1 RNA caused by a lack of overlap with the right arm and the tip of the left arm. This can potentially be attributed to the difference in length between the solution scattering sequence (280 nts) and the secondary structure prediction sequence (301 nts). The difference can be explained by construct synthesis whose sequence lacked 41 nts at the 3'-end but encompassed the remaining 80% of the secondary structure sequence predicted which still comprises the core and majority of the SAXS structure. Nevertheless, both structures detail the presence of the secondary structures identified previously, and their orientations. Applying both solution scattering techniques and coarse-grained computational modelling reveals that LincRNA-p21 Alu Inverted Repeats do not adopt completely stable, single-representative structures due in part to the conformational flexibility present in their respective DAMMIN and SimRNA models. Both the sense and antisense AluSx1 RNAs adopt multiple conformations, however, they closely approximate into a generally similar, single-representative structure with mild conformational and structural differences when averaged. The main shape – one that is elongated, asymmetrical, with regions that encompass the main left and right arms, and three-way junction – is uniform and preserved throughout solution scattering and computational fitting techniques. Consequently, applying a combination of SAXS and computationally generated tertiary structure models concertedly determined appropriate representations of the LincRNA-p21 *AluSx1* Inverted Repeats.

5.0 Conclusion

We have demonstrated that chemical probing techniques involved in RNA secondary structure predictions such as SHAPE can be combined using a multifaceted biophysical approach involving SAXS, AUC, SEC-MALS and computational RNA modelling. Three-dimensional models are important in confirming secondary structure motifs that are predicted through probing techniques. By expanding the structure to include three-dimensional native state folding, essential regulatory RNAs involved in apoptosis and tumour suppression in cancer cells can be effectively visualised to identify functional domains and potential RNA-Protein binding regions.
